## **Statistical Laws of Random Strained Vortices in Turbulence**

Nozomu Hatakeyama and Tsutomu Kambe

Department of Physics, University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113, Japan

(Received 24 April 1997)

Statistical properties of random distribution of strained vortices (Burgers' vortices) in turbulence are studied, and the scaling behavior of structure functions is investigated. It is found within the scale range of interest (corresponding to the inertial range) that the third-order structure function is negative and the scaling exponent is nearly unity in accordance with Kolmogorov's four-fifths law. The inertial-range scaling exponents are estimated up to the 25th order, which are in good agreement with those obtained from experiments and direct numerical simulations once the probability distribution of the vortex strength is taken into account. PACS numbers: 47.27.Gs, 47.27.Jv, 47.32.Cc

In recent computer simulations and experiments of homogeneous isotropic turbulence at high Reynolds numbers, a number of elongated intense vortex structures are observed to distribute randomly in space, which are often called *worms* [1–5]. Each worm structure is found to be approximately a Burgers' vortex under local straining and is responsible for the signals usually referred to as the *intermittency* [5]. Bearing this in mind, we investigate the statistical properties of a model field associated with the random distribution of Burgers' vortices.

High Reynolds number flows are characterized by the statistical properties of the velocity field  $\boldsymbol{v}(\boldsymbol{x})$  and the difference at two points  $\boldsymbol{x}$  and  $\boldsymbol{x} + \boldsymbol{s}$ :  $\Delta \boldsymbol{v}(\boldsymbol{x}, \boldsymbol{s}) = \boldsymbol{v}(\boldsymbol{x} + \boldsymbol{s}) - \boldsymbol{v}(\boldsymbol{x})$ . Defining the *longitudinal* difference in the direction  $\boldsymbol{s}$  by

$$\Delta \boldsymbol{v}_{\ell}(\boldsymbol{x},\boldsymbol{s}) = \Delta \boldsymbol{v}(\boldsymbol{x},\boldsymbol{s}) \cdot \frac{\boldsymbol{s}}{\boldsymbol{s}}, \qquad (1)$$

where s = |s|, the *p*th-order longitudinal structure function  $S_p$  is given by  $S_p = \langle (\Delta v_\ell)^p \rangle$ , where  $\langle \cdot \rangle$  is an ensemble average for a fixed *s*. In the homogeneous isotropic turbulence, the structure function  $S_p$  follows a power law in the inertial range of *s*:

$$S_p(s) \equiv \langle [\Delta v_\ell(\mathbf{x}, \mathbf{s})]^p \rangle \sim s^{\zeta_p}, \tag{2}$$

where  $\zeta_p$  is the scaling exponent of the *p*th-order structure function.

The skewness  $S_3/(S_2)^{3/2}$  in turbulence is always found to be negative for small *s*. The *negative* skewness is related to the enstrophy production [6] and the non-Gaussian statistics of the velocity derivatives [7]. An example of a vortex under external straining (considered below) has such negative skewness. In particular, the third-order structure function is described by Kolmogorov's four-fifths law [8,9],

$$\langle (\Delta v_{\ell})^3 \rangle = -\frac{4}{5} \varepsilon s = -\frac{4}{5} \nu \overline{\omega}^2 s,$$
 (3)

for the values of s in the inertial range, where the rate of energy dissipation  $\varepsilon$  is replaced by an equivalent form  $\varepsilon = \nu \overline{\omega}^2$ ,  $\overline{\omega}$  being the rms vorticity. The parameter  $\varepsilon$  may be termed more appropriately as the energy transfer across a wave number in the inertial range. In Kolmogorov 1941 theory [10], the average  $\langle |\Delta v_{\ell}| \rangle$  at the scale *s* in the inertial range is given by dimensional arguments as  $\langle |\Delta v_{\ell}| \rangle \sim (\varepsilon s)^{1/3}$ , and, in general, the exponent  $\zeta_p$  is represented as  $\zeta_p = p/3$  (referred to as K41 below).

According to the scenario of Kambe and Hosokawa [11], the present analysis aims at clarifying statistical properties of a mathematical model endowed with a characteristic of the isotropic homogeneous turbulence, namely a random system of strained vortices. This approach is consistent with the idea of the multifractal model of turbulence field. It is assumed that, in the limit of large Reynolds numbers, there is an invariant measure of the Navier-Stokes turbulence, for which a probability distribution function  $P(s, \Delta v_{\ell})$  is defined [9]. The *p*th-order structure function  $S_p$  is expressed as an integral  $S_p(s) = \int (\Delta v_{\ell})^p P(s, \Delta v_{\ell}) d\Delta v_{\ell}$ , which leads to a power law in a certain interval of *s* corresponding to the inertial range, as actually obtained below for the present model.

Recently a phenomenological step was advanced [12–14]. This is a statistical model taking into account a hierarchy of fluctuating vortex-filament structures which is found to have properties of the *log-Poisson* statistics. The resulting exponent of the *p*th-order structure function is given as  $\zeta_p = p/9 + 2 - 2(2/3)^{p/3}$ , which is found to be near the direct numerical simulation (DNS) [1] and the experimental observation [15,16].

Turbulence is regarded as a field of rate of strain. At each point, three principal rates of strain,  $\alpha$ ,  $\beta$ , and  $\gamma$ , are defined, and they satisfy the relation  $\alpha + \beta + \gamma = 0$ by the solenoidality of the velocity field. Assuming the property  $\alpha \ge \beta \ge \gamma$ , we always have  $\alpha \ge 0$  and  $\gamma \le 0$ . The intermediate eigenvalue  $\beta$  takes either a positive or negative value.

We consider a velocity field of a strained vortex. The vorticity distribution is assumed to have only the axial component  $\omega(r)$  in the cylindrical coordinate system

 $(r, \theta, z)$ . Hence the vorticity vector is  $\boldsymbol{\omega} = (0, 0, \boldsymbol{\omega}(r))$  with the axial component  $\boldsymbol{\omega}(r)$  specified later. The velocity associated with  $\boldsymbol{\omega}$  is  $\boldsymbol{v}_{\boldsymbol{\omega}} = (0, \boldsymbol{v}_{\theta}(r), 0)$ , having only the azimuthal component  $\boldsymbol{v}_{\theta}(r)$ . This vortex is exposed to an irrotational straining field given by  $\boldsymbol{v}_e = (-ar, 0, 2az)$  satisfying the solenoidal property. The total flow field  $\boldsymbol{v}$  is the superposition of  $\boldsymbol{v}_{\boldsymbol{\omega}}$  and  $\boldsymbol{v}_e$ :

$$\boldsymbol{v}(\boldsymbol{x}) = (-ar, \boldsymbol{v}_{\theta}(r), 2az). \tag{4}$$

Local principal rates of strain  $e_1$ ,  $e_2$ , and  $e_3$  of the velocity field  $\boldsymbol{v}(\boldsymbol{x})$  are readily calculated as  $e_1 = -a + |e_{r\theta}|$ ,  $e_2 = 2a$ , and  $e_3 = -a - |e_{r\theta}|$ , where  $e_{r\theta} = [\boldsymbol{v}_{\theta}'(r) - r^{-1}\boldsymbol{v}_{\theta}(r)]/2$ . If |a| is sufficiently small compared with  $|e_{r\theta}|$ , then  $\alpha = e_1$ ,  $\beta = e_2$ , and  $\gamma = e_3$ . In the following, the parameter a is assumed to be positive.

In this circumstance, it can be shown [17] that, with an arbitrary initial axisymmetric distribution, the axial vorticity  $\omega(r)$  (only nonzero component) tends to the final steady distribution  $\omega_B(r)$  asymptotically as  $t \to \infty$ :

$$\omega_B(r) = \frac{\Gamma}{\pi r_b^2} \exp(-\hat{r}^2),$$
  

$$\upsilon_\theta(r) = \frac{\Gamma}{2\pi r_b} \frac{1 - \exp(-\hat{r}^2)}{\hat{r}},$$
(5)

where  $\hat{r} = r/r_b$ ,  $r_b = (2\nu/a)^{1/2}$ , and  $\Gamma$  is the strength. This is the *Burgers' vortex* of radius  $r_b$  [18] (Fig. 1).

The vortex axes are randomly oriented spatially in isotropic turbulence. In the present single-worm case, the average is taken over a sphere centered at a chosen reference point  $\mathbf{x}$ . For example, local third-order moment  $\hat{s}_3 = \langle (\partial \boldsymbol{v}_{\ell}/\partial s)^3 \rangle_{sp} |_{s=0}$  (skewness without normalization) of the longitudinal derivative at  $\mathbf{x}$  is calculated [19,20] as  $\hat{s}_3 = (8/35)e_1e_2e_3 = -(16/35)a(e_{r\theta}^2 - a^2)$ , where the spherical average  $\langle \cdot \rangle_{sp}$  is an integral over the solid angle with respect to the direction s divided by  $4\pi$ . It is found that, for a pure vortex  $\boldsymbol{v}_{\omega}$  without any ex-

FIG. 1. The local energy dissipation rate  $\varepsilon_{\text{loc}}$ , the axial vorticity  $\omega_B$ , and the azimuthal velocity  $v_{\theta}$  of the Burgers' vortex for  $R_{\Gamma} \equiv \Gamma/\nu = 2000$  normalized by  $\nu = 0.1$ .

ternal strain (hence a = 0),  $\hat{s}_3$  is zero, while the converse case of a pure straining  $\boldsymbol{v}_e$  without the vortex (thus  $e_{r\theta} = 0$ ),  $\hat{s}_3 = (16/35)a^3$  is positive. However, the composite flow field considered above gives a negative  $\hat{s}_3$  as far as  $|e_{r\theta}| > a$ . Therefore the space surrounding the intense vortex under the straining of  $\boldsymbol{v}_e$ is characterized as a field of negative skewness. The local rate of energy dissipation is given as  $\varepsilon_{\rm loc}(r) =$  $\nu \{12a^2 + (2e_{r\theta})^2\}$ , where  $2e_{r\theta} \equiv v_{\theta}^{T}(r) - r^{-1}v_{\theta}(r) = (\Gamma/\pi r_b^2) \{\exp(-\hat{r}^2) - \hat{r}^{-2}[1 - \exp(-\hat{r}^2)]\}$ . If  $\Gamma/(\pi r_b^2)$ is sufficiently large compared with a, the energy is strongly dissipated at about  $r_b$ , while at the center of the vortex it is scarcely dissipated. Taking an average of the local third-order moment over a spherical surface of radius s = |s|, we have  $\langle (\Delta v_\ell)^3 \rangle_{sp} \approx \hat{s}_3 s^3$ when s is sufficiently small. Owing to the solenoidal property of the velocity, the average  $\langle \Delta v_\ell 
angle_{
m sp}$  vanishes identically.

Next, we investigate the behavior of the longitudinal velocity difference  $\Delta v_{\ell}(s)$  at large distances, in particular, the general *p*th-order structure functions. Fixing a reference point x at  $(r_0, 0, z_0)$  in the cylindrical system  $K_1$   $(r, \theta, z)$ , we define spherical polar coordinates  $K_2$   $(s, \zeta, \phi)$  centered at x to represent the relative position of the point x + s, where  $\zeta$  is the polar angle and  $\phi$  is the azimuthal angle. For the velocity field (4) and (5), the longitudinal velocity difference is represented as

$$\Delta v_{\ell}(\boldsymbol{x}, \boldsymbol{s}, \boldsymbol{\zeta}, \boldsymbol{\phi}) = a \boldsymbol{s} (3 \cos^2 \boldsymbol{\zeta} - 1) + r_0 W(r, r_0) \sin \boldsymbol{\zeta} \sin \boldsymbol{\phi} , \quad (6)$$

where  $W(r, r_0) = r^{-1} v_{\theta}(r) - r_0^{-1} v_{\theta}(r_0)$ . The spherical average is calculated by

$$\langle (\Delta \boldsymbol{v}_{\ell})^{p} \rangle_{\rm sp}(\boldsymbol{x}, s) \equiv \frac{1}{4\pi} \int_{-\pi}^{\pi} d\phi \int_{0}^{\pi} (\Delta \boldsymbol{v}_{\ell})^{p} \sin \zeta d\zeta \,.$$
(7)

This average will depend on the point x as well as the separation vector s and have different scaling behaviors with respect to s at different x's, in accordance with the multifractal aspect.

The statistical average  $\langle \cdot \rangle$  is taken first by the spherical average  $\langle \cdot \rangle_{sp}$  with respect to the running point x + s, and second by the volume average with respect to the reference point x:

$$\langle \cdot \rangle(s) = \frac{1}{\pi R_0^2 \Delta z} \int_0^{\Delta z} dz_0 \int_0^{R_0} \langle \cdot \rangle_{\rm sp} 2\pi r_0 dr_0 \qquad (8)$$

(the average with respect to  $z_0$  is trivial). Thus we obtain the statistical properties of isotropy and homogeneity from the velocity field (4).

The structure functions are estimated for three different strengths of the Burgers' vortex with  $R_{\Gamma} \equiv \Gamma/\nu = 600$ , 2000, and 10 000. In Fig. 2, the third-order structure

FIG. 2. The third-order structure functions times -1 for  $R_{\Gamma} = 600, 2000, 10\,000$  with  $\nu = 1$ . Straight lines with unit slope are obtained from Kolmogorov's four-fifths law (3).

functions are shown. At small distances  $s/r_b < 1$ , the function  $S_3(s)$  is proportional to  $s^3$  as anticipated for the continuous smooth field. However, for  $s/r_b > 1$  the function  $S_3(s)$  shifts to another scaling law of a different slope. It is found that the third-order scaling exponent  $\zeta_3$  in the second scaling range is about unity and almost independent of the magnitude of  $R_{\Gamma}$ . Straight lines with unit slope are obtained from Kolmogorov's four-fifths law (3), where the mean energy dissipation rate is defined as  $\varepsilon = (\pi R_0^2)^{-1} \int_0^{R_0} \varepsilon_{\text{loc}}(r_0) 2\pi r_0 dr_0$ . The limit of the  $r_0$  integral is given by  $R_0 = 2.5r_b$  so as to be consistent with the four-fifths law for the second scaling range. The first scaling range of the exponent 3 is identified as the viscous range, and the second range of the exponent 1 is identified as the inertial range which is wider for larger  $R_{\Gamma}$ . In Fig. 3, the scaling exponents  $\zeta_p$  up to p = 25are shown for the three values of  $R_{\Gamma}$ , and compared with those of K41 and the log-Poisson model. Increasing

FIG. 3. The exponents  $\zeta_p$  of the structure functions for  $R_{\Gamma} = 600, 2000, 10\,000$  with K41 [10] and the log-Poisson model [12–14].

the magnitude of  $R_{\Gamma}$ , the exponents  $\zeta_p$  decrease more below the K41's. The even-*p* exponents fall lower than the line of the odd-*p* exponents, which is in agreement with the general behavior of the experimental data [15].

The probability distribution functions of the vortex Reynolds number  $R_{\Gamma}$  and the Burgers' radius  $r_b$  in turbulence are estimated by Jimenéz et al. [2] in DNS and by Belin et al. [5] experimentally. In particular, distributions of the normalized values  $R_{\Gamma}/R_{\lambda}^{1/2}$  are independent of the Reynolds number  $R_{\lambda}$  based on the Taylor microscale  $\lambda$ . Taking the probability distribution into account, the structure functions are estimated [21]. In Figs. 4 and 5, the behaviors of such structure functions are illustrated. It is observed that there exist two scaling ranges in each structure function, in which the second one corresponds to the inertial range. Here the inertial range is defined as the range within which the variance of the third-order structure function, with respect to the four-fifths law, is least. In Fig. 6, the scaling exponents in the inertial range are plotted and compared with those obtained from other models, DNS, and experiments. It is found that the present analysis can predict the scaling exponents which are remarkably coincident with those of DNS [1] and the experiments [15,16].

If the vortex is absent (therefore  $v_{\theta} = 0$ ), we have  $S_p(s) = C_p a^p s^p \propto s^p$  from Eqs. (6) and (7), where  $C_p$  is a constant. On the other hand, if the external strain is absent (therefore a = 0), we find that the structure functions of the odd order are identically zero by the antisymmetric property of Eq. (6). Hence the present scaling exponents consistent with the homogeneous isotropic turbulence have resulted from the combined field of the vortex and the turbulence straining.

FIG. 4. The first-, second-, and third-order structure functions for  $R_{\lambda} = 2000$ . The region between the dotdashed lines is regarded as inertial range. The solid line is given by Kolmogorov's four-fifths law (3) with  $\varepsilon = (\pi R_0^2)^{-1} \int_0^\infty dR_{\Gamma} \int_0^{R_0} \varepsilon_{\rm loc}(R_{\Gamma}, r) P(R_{\Gamma}) 2\pi r dr$ , and dashed lines are the least-log-square fits within the inertial range.

FIG. 5. High-order structure functions with fitting lines in the inertial range for  $R_{\lambda} = 2000$ .

The present study is summarized as follows.

(1) It is found from the velocity field of a random distribution of Burgers' vortices that the third-order structure function is negative in the inertial range and the scaling exponent is nearly unity and independent of the vortex Reynolds number  $R_{\Gamma}$ , and that the second-order structure function has the scaling exponent of about two-thirds, in accordance with the general turbulence properties.

(2) The scaling exponents of the high-order structure functions deviate increasingly below K41 as  $R_{\Gamma}$  becomes larger. A Burgers' vortex in turbulence causes, more and more, the degree of intermittency in the field as its strength gets larger.

(3) The scaling exponents  $\zeta_p$  are in good agreement with the experiments and DNS data once the probability

FIG. 6. The exponent  $\zeta_p$  of the structure function for  $R_{\lambda} = 2000$  with K41 [10], log-Poisson model [12–14], DNS for  $R_{\lambda} = 200$  by Vincent and Meneguzzi [1], a wind tunnel experiment for  $R_{\lambda} = 200$  by Stolovitzky *et al.*, obtained from taking the pollution of viscous range into account [15], and a helium gas experiment for  $R_{\lambda} = 2000$  by Belin *et al.*, obtained by use of extended self-similarity [16].

distribution of  $R_{\Gamma}$  (taken from experiment and DNS) is taken into account.

- [21] In order to estimate the mean vortex Reynolds number, it is assumed for isotropic turbulence that  $\sigma = v_{\rm rms}/\lambda$ and  $\Gamma = 2\pi r_b v_{\rm rms}$ , where  $\sigma$  is the axial stretching rate of worm ( $\sigma = 2a$  in the case of Burgers' vortex) and  $v_{\rm rms}$  the root-mean-square velocity. The consequence is  $R_{\Gamma}/R_{\lambda}^{1/2} = 4\pi$ , in good agreement with the value obtained by Jimenéz *et al.* in DNS [2]. Thus the probability distribution function (PDF) of  $R_{\Gamma}$  is defined as  $P(R_{\Gamma}) = (C^3/2)R_{\Gamma}^2 \exp(-CR_{\Gamma})$  with  $C = (3/4\pi)R_{\lambda}^{1/2}$ , so that the mean value of  $R_{\Gamma}$  is  $4\pi R_{\lambda}^{1/2}$  and the PDF has the similar form as DNS [2] and experiment [16], especially in the limit of  $R_{\Gamma} \to 0, \infty$ .
